15.14 Projects

for determining the quality of a random number generator for a particular application. The difficulty is that the quality of a random number generator for a specific application depends in part on how the subtle correlations that are intrinsic to all deterministic random number generators couple to the way that the random number sequences are used. In this project we explore the quality of two random number generators when they are used to implement single spin flip dynamics (the Metropolis algorithm) and single cluster flip dynamics (Wolff algorithm) for the two-dimensional Ising model.

(a) Write methods to generate sequences of random numbers based on the linear congruential algorithm

$$x_n = 16,807x_{n-1} \mod (2^{31} - 1),$$
 (15.81)

and the generalized feedback shift register (GFSR) algorithm

$$x_n = x_{n-103} \oplus x_{n-250}. (15.82)$$

In both cases  $x_n$  is the *n*th random number. Both algorithms require that  $x_n$  be divided by the largest possible value of  $x_n$  to obtain numbers in the range  $0 \le x_n < 1$ . The GFSR algorithm requires bit manipulation. Which random number generator does a better job of passing the various statistical tests discussed in Problem 7.35?

- (b) Use the Metropolis algorithm and the linear congruential random number generator to determine the mean energy per spin E/N and the specific heat (per spin) C for the L=16 Ising model at  $T=T_c=2/\ln(1+\sqrt{2})$ . Make ten independent runs (that is, ten runs that use different random number seeds) and compute the standard deviation of the means  $\sigma_m$  from the ten values of E/N and C, respectively. Published results by Ferrenberg, Landau, and Wong are for  $10^6$  Monte Carlo steps per spin for each run. Calculate the differences  $\delta_e$  and  $\delta_c$  between the average of E/N and C over the ten runs and the exact values (to five decimal places), E/N=-1.45306 and C=1.49871. If the ratio  $\delta/\sigma_m$  for the two quantities is order unity, then the random number generator does not appear to be biased. Repeat your runs using the GFSR algorithm to generate the random number sequences. Do you find any evidence of statistical bias?
- (c) Repeat part (b) using Wolff dynamics. Do you find any evidence of statistical bias?
- (d) Repeat the computations in parts (b) and (c) using the random number generator supplied with your programming language.

## Project 15.35 Nucleation and the Ising model

(a) Equilibrate the two-dimensional Ising model at  $T=4T_c/9$  and B=0.3 for a system with  $L\geq 50$ . What is the equilibrium value of m? Then flip the magnetic field so that it points down, that is, B=-0.3. Use the Metropolis algorithm and plot m as a function of the time t (the number of Monte Carlo steps per spin). What is the qualitative behavior of m(t)? Does it fluctuate about a positive value for a time long enough to determine various averages? If so, the system can be considered to have been in a metastable state. Watch the spins evolve for a time before m changes sign. Visually determine a place in the lattice where a "droplet" of the stable phase (down

spins) first appears and then grows. Change the random number seed and rerun the simulation. Does the droplet appear in the same spot at the same time? Can the magnitude of the field be increased further, or is there an upper bound above which a metastable state is not well defined?

- (b) As discussed in Project 15.32, we can define clusters of spins by placing a bond with probability p between parallel spins. In this case there is an external field and the proper definition of the clusters is more difficult. For simplicity, assume that there is a bond between all nearest neighbor down spins and find all the clusters of down spins. One way to identify the droplet that initiates the decay of the metastable state is to monitor the number of spins in the largest cluster as a function of time after the quench. At what time does the number of spins in the largest cluster begin to grow quickly? This time is an estimate of the nucleation time. Another way of estimating the nucleation time is to follow the evolution of the center of mass of the largest cluster. For early times after the quench, the center of mass position has large fluctuations. However, at a certain time these fluctuations decrease considerably, which is another criterion for the nucleation time. What is the order of magnitude of the nucleation time?
- (c) While the system is in a metastable state, clusters of down spins grow and shrink randomly until eventually one of the clusters becomes large enough to grow, nucleation occurs, and the system decays to its stable macroscopic state. The cluster that initiates this decay is called the nucleating droplet. This type of nucleation is due to spontaneous thermal fluctuations and is called homogeneous nucleation. Although the criteria for the nucleation time that we used in part (b) are plausible, they are not based on fundamental considerations. From theoretical considerations the nucleating droplet can be thought of as a cluster that just makes it to the top of the saddle point of the free energy that separates the metastable and stable states. We can identify the nucleating droplet by using the fact that a saddle point structure should initiate the decay of the metastable state 50% of the time. The idea is to save the spin configurations at regular intervals at about the time that nucleation is thought to have occurred. We then restart the simulation using a saved configuration at a certain time and use a different random number sequence to flip the spins. If we have intervened at a time such that the largest cluster decays in more than 50% of the trials, then the intervention time (the time at which we changed the random number seed) is before nucleation. Similarly, if less than 50% of the clusters decay, the intervention is after the nucleation time. The nucleating droplet is the cluster that decays in approximately half of the trial interventions. Because we need to do a number of interventions (usually in the range 20–100) at different times, the intervention method is much more CPU intensive than the other criteria. However, it has the advantage that it has a sound theoretical basis. Redo some of the simulations that you did in part (b) and compare the different estimates of the nucleation time. What is the nature and size of the nucleating droplet? If time permits, determine the probability that the system nucleates at time t for a given quench depth. (Measure the time t after the flip of the field.)
- (d) Heterogeneous nucleation occurs in nature because of the presence of impurities, defects, or walls. One way of simulating heterogeneous nucleation in the Ising model is to fix a certain number of spins in the direction of the stable phase (down). For
